Abstract

Introduction: Near-infrared spectroscopy (NIRS) non-invasively detects changes in the concentration of the chromophores oxygenated (\(\Delta O_2Hb\)) and deoxygenated hemoglobin (\(\Delta HHb\)) as the bladder detrusor muscle contracts during voiding. Such data provide novel information on bladder oxygenation and hemodynamics. We evaluated the feasibility of monitoring ambulant subjects using a wireless NIRS device.

Methods: The wireless device uses paired light-emitting diodes (wavelengths 760 and 850 nm) and a silicon photodiode detector. We monitored 14 asymptomatic subjects (10 adults, 4 children) and 6 symptomatic children with non-neurogenic lower urinary tract dysfunction (NLUTD) during spontaneous voiding after natural filling. The device was taped to the abdominal skin 2 cm above the symphysis pubis across the midline. The wireless NIRS data (patterns of change in chromophore concentration) were compared between subjects and to the data obtained using a laser-powered instrument.

Results: Graphs of \(\Delta O_2Hb\), \(\Delta HHb\), and total hemoglobin (\(\Delta tHb\)) were obtained from all 20 patients. Data during uroflow showed reproducible patterns of bladder chromophore change between asymptomatic subjects (rise in \(\Delta tHb/\Delta O_2Hb\)), consistent with laser instrument data. In contrast, all 6 symptomatic children had a negative trend in \(\Delta tHb\), with falls in \(\Delta O_2Hb\). One adult experienced “shy” bladder and changes in hemodynamics/oxygenation occurred while bladder volume was unchanged.

Conclusions: Wireless NIRS bladder monitoring is feasible in ambulant adults and children; wireless and laser-derived data in asymptomatic subjects are comparable. Pilot data suggest that subjects with symptomatic NLUTD have impaired bladder oxygenation/hemodynamics. The fact that chromophore changes occur when bladder volume remains constant supports the concept that NIRS data are a physiologic measure.

Changes in tissue oxygenation and hemodynamics can be monitored using near-infrared spectroscopy (NIRS) by following variations in concentration of the chromophores oxygenated hemoglobin (\(\Delta O_2Hb\)) and reduced hemoglobin (\(\Delta HHb\)) and changes in total hemoglobin (\(\Delta tHb\)) \([O_2Hb + HHb]\). There are many reports on the physics principles involved, the differences in absorption spectra of hemoglobin when oxygenated and deoxygenated, the range of research studies where NIRS technology has been successfully applied.1-3 In brain and muscle clinical applications, the patterns of chromophore changes differ in healthy and diseased humans according to the physiologic consequences of disease pathology.1,2 Recent urologic applications of NIRS include research using single-channel continuous wave4 (CW) and functional NIRS5 (fNIRS) methodologies to monitor changes in chromophore concentration within the bladder detrusor as the organ fills and empties. NIRS monitoring can be done simultaneously with pressure flow studies (urodynamic studies [UDS]), and provides urologists with previously unavailable insights into the hemodynamics of the detrusor microcirculation and oxygen supply and demand in the context of voiding.6

In men with lower urinary tract symptoms (LUTS) simultaneous UDS and NIRS studies identified different patterns of change in \(\Delta O_2Hb\) and \(\Delta HHb\) in those with and without bladder outlet obstruction (BOO). In addition to the physiologic information provided by the NIRS data, two diagnostic algorithms incorporating NIRS parameters gave comparable discriminant ability for the presence or absence of BOO as the Abrahams-Griffiths nomogram.4,7 Independent investigators8 initially validated the diagnostic ability of the original algorithm which incorporates the trend of \(\Delta O_2Hb\) (positive or negative) \(Q_{max}\) and residual volume.4 Recently, Chung and colleagues’ second study suggested the algorithm’s \(\Delta O_2Hb\) trend component warrants improvement.9 The sec-
Ambulant monitoring of bladder oxygenation and hemodynamics

We recruited a convenience sample of 10 healthy asymptomatic adult males (age range: 24-65 years) and 10 children (4 asymptomatic and 6 symptomatic attending a University clinic for investigation of non-neurogenic lower urinary tract dysfunction non-neurogenic lower urinary tract dysfunction (NLUTD) [age range: 5-11 years]). Urine microscopy and cultures were not part of the evaluation of symptomatic subjects at this visit (all had had negative tests previously); also no patients were on antimuscarinics. We obtained signed consent forms and our study was approved by our University ethical review board.

Protocol

Each subject spontaneously emptied his/her bladder, and then had water to drink ad libitum so that the bladder could fill naturally. The device was attached to the abdominal wall using medical adhesive tape with the emitters/sensor 2 cm superior to the symphysis pubis and across the midline, and secured by a retaining strap. Subjects were then able to be fully ambulant and in a separate room remote from the investigator. Asymptomatic subjects were studied with NIRS during uroflow. In symptomatic children NIRS was conducted simultaneously with the regular urologic studies planned for the clinic visit (uroflow and EMG).

Changes in chromophore concentration in the bladder during spontaneous bladder emptying were monitored with pre- and post-voiding baseline data collection. To void, adult subjects were asked to stand still and children to sit; permission was then given to empty the bladder, with the instruction to do so normally without abdominal straining.

Graphs of change in $\Delta O_2Hb$, $\Delta HHb$ and $\Delta tHb$ from baseline timed at permission to void were compared between subjects; also, trends of change (positive or negative) were compared between asymptomatic and symptomatic children. The asymptomatic adult data was also compared to data collected using a conventional laser-powered instrument and with the same study protocol and software algorithm.

Results

Complete NIRS data sets were obtained for all 20 subjects. No technical difficulties were encountered, and all subjects were able to be ambulant, except during the voiding segment of the protocol. During uroflow, the patterns of change in chromophore concentration were comparable in all 14 asymptomatic subjects. One adult had a “shy bladder” and experienced a delay following permission to void that lasted 137 seconds; however, from uroflow start, his pattern of chromophore change matched other asymptomatic subjects. The 9 adults and 4 children who voided promptly showed an initial increase in $\Delta tHb$ after permission to void and a progressive rise during uroflow up to the point of peak urine flow, with a gradual decline thereafter. The increase in $\Delta tHb$ was predominantly due to an increase in $\Delta O_2Hb$. This pattern of change was comparable to data collected in normal adults using a laser powered NIRS instrument in prior studies.1 Representative graphs of this pattern from the wireless/LED device and a conventional/laser instrument are available (Fig. 1).

In the adult with the “shy” bladder, the typical brief initial rise in $\Delta tHb$ and $\Delta O_2Hb$ following permission to void was evident, however during the subsequent delay prior to uroflow variations in detrusor hemodynamics and oxygen, supply and demand were evident, while his bladder

Methods

Instrumentation

The wireless device (Portamon, Artinis Medical Technologies, BV, The Netherlands) was designed for muscle exercise physiology protocols.14 Its key technical features include: miniaturization (dimensions $83 \times 52 \times 20$ mm; weight 84 g); 3 paired LEDs as the NIR light source (LED wavelengths 760 and 850 nm); a silicon photodiode detector screened against ambient light; data collection at 10 Hz; a rechargeable lithium polymer battery; a 2-mb internal memory; and Bluetooth technology.

Raw optical data can be stored during ambulant measurement or broadcast to a laptop computer; graphs to illustrate changes in $\Delta O_2Hb$, $\Delta HHb$ and $\Delta tHb$ [$O_2Hb + HHb$] can be plotted.

Subjects

Our results are available (Fig. 1).
volume remained constant. We have illustrated data during this period with two episodes of movement-generated artifact removed to clarify the data trends (Fig. 2). From 32 seconds, \( \Delta tHb \) and \( \Delta O2Hb \) progressively rose as urge without uroflow continued. This indicated an increase in oxygenated blood volume in the detrusor microcirculation. From 52 seconds, \( \Delta O2Hb \) declined and \( \Delta HHb \) progressively rose. This indicated an increased rate of oxygen consumption, with the fall in \( \Delta tHb \) from 77 to 92 seconds indicating an associated fall in blood volume. From 92 seconds, \( tHb \) rose, predominantly due to increasing HHB, and \( \Delta HHb \) became greater than \( \Delta O2Hb \), indicating oxygen consumption exceeded oxygen supply as ongoing urge without uroflow continued. The \( \Delta HHb \) continued to rise until 135 seconds. However, from 114 seconds, a sustained rise in \( \Delta tHb \) occurred due to a marked increase in \( \Delta O2Hb \), and \( \Delta O2Hb \) became greater than \( \Delta HHb \) just prior to uroflow start. This implied a hemodynamic response with provision of increased oxygenated blood volume which was followed by successful voiding.

Fig. 1. Changes in chromophore concentration from permission to void to uroflow end in asymptomatic adults obtained with A: The wireless NIRS device with light emitting diodes as the NIR source; and B: A conventional laser powered NIRS instrument. Both graphs show the pattern of chromophore change common to asymptomatic subjects: an increase in \( \Delta tHb \) following permission to void predominantly reflecting an increase in \( \Delta O2Hb \), then during uroflow \( \Delta tHb \) and \( \Delta O2Hb \) continue to increase, while the deoxygenated hemoglobin concentration shows minimal change or no change.
The 6 children diagnosed with NLUTD\textsuperscript{15} had pilot NIRS data different from the asymptomatic children (Table 1). Fig. 3 shows representative graphs of the pattern of chromophore change from an asymptomatic child (part A) and subjects 1 to 5 (Table 1) with symptoms of NLUTD (part B). In part A, the pattern and positive trend for $\Delta tHb$ and $\Delta O_2Hb$ matched those seen in asymptomatic adults (Fig. 1). In part B, there was little or no increase in $tHb$ following permission to void, and a downward trend was associated with a progressive fall in $\Delta O_2Hb$ during uroflow. This negative trend implied an overall reduction in the detrusor blood volume and the availability of oxygenated hemoglobin over the course of voiding. Figure 4 shows simultaneous urologic and NIRS data in a symptomatic child (subject 6). Here, abnormalities in uroflow were associated with a simultaneous increase in $\Delta O_2Hb$ and $\Delta HHb$ following permission to void and fluctuations in the negative trend in $\Delta tHb$ during uroflow were due to variations in $\Delta O_2Hb$.

Insufficient subjects were recruited in this feasibility study to calculate the specificity and sensitivity of the NIRS data, as has been possible in prior studies of patients with and without BOO\textsuperscript{4,7,8} and by Farag and colleagues when using NIRS as a diagnostic entity for DO\textsuperscript{11}.

Children readily accepted the device, wore it without complaint and continued to be fully ambulant prior to and after the voiding component of the study. Secure skin attachment was achieved in all adults and children, which prevented movement of the device even when subjects were ambulant.

BMI: body mass index; PVR: post-void residual; UTI: urinary tract infection.
This study indicates that NIRS monitoring of the bladder is feasible using a wireless device. During voiding, asymptomatic adults had patterns of change in chromophore concentration that matched those in asymptomatic children, and were consistent with results obtained with a laser powered instrument. Pilot data from children suggest that those with NLUTD have a different chromophore pattern to asymptomatic children. Physiologically, this appears due to impairment of detrusor hemodynamics and oxygenation, based on comparable NIRS changes seen in voluntary muscle. If further studies confirm these findings, NIRS may contribute to a greater understanding of the physiology underlying their
Ambulant monitoring of bladder oxygenation and hemodynamics

Symptoms of urgency, weak flow and retention of urine.

Confidence for NIRS monitoring physiologic change in the detrusor comes from the physics of spectroscopy, chromophore changes only being detected over the bladder during voiding events, and data mirroring observations in other tissue (e.g., during hypoxia or ischemia). Natural voiding requires detrusor contraction, which in turn requires provision of sufficient oxygenated blood to meet oxygen demand. And it is becoming evident that where factors exist that adversely affect detrusor muscle function or the bladder’s microcirculation, different patterns of chromophore change are observed during voiding to those seen in asymptomatic subjects. Such patterns include a falling $\Delta$O$_2$Hb and/or increasing $\Delta$HHb (which implies altered oxygen supply/demand), and compromised tHb (indicative of impaired hemodynamics).

In this context, data from the subject with a “shy” bladder provide additional evidence that NIRS-derived chromophore changes reflect physiologic variations occurring in the detrusor microcirculation rather than artifact or movement.

Fig. 4. Simultaneous data (uroflow, EMG, voided volume, and NIRS pattern of chromophore change in a child with symptoms of non-neurogenic lower urinary tract dysfunction. Following permission to void an initial increase in $\Delta$tHb occurs due to an equal increase of $\Delta$O$_2$Hb and $\Delta$HHb; a sharp decrease in $\Delta$tHb is then evident predominantly due to a fall in $\Delta$O$_2$Hb that continues as uroflow starts, periodic increases in $\Delta$HHb/$\Delta$O$_2$Hb occur, but the trend is negative during voiding particularly from 23 seconds, while $\Delta$HHb remains stable. This chromophore pattern implies a failure of oxygen supply to meet demand following permission to void followed by hemodynamic fluctuation with variations in the availability of O$_2$Hb and total blood volume in the detrusor during voiding.

**Dysfunctional Voiding**

---

**Uroflow Summary:**

- Max. flow: 33.7 ml/s
- Mean flow: 8.2 ml/s
- Voiding time: 31 s
- Acceleration: 1 ml/s
- Flow time: 23 s
- Voided Volume: 190 ml
- PVR: 19 ml

---

- P - Permission to void
- S - Urine flow starts
- Q - Peak urine flow
- E - Uroflow ends

---

- Total Hb
- Deoxygenated Hb
- Oxygenated Hb

---
Between permission to void and uroflow start, the patient was unable to void in spite of sustained urge, most probably associated with spontaneous isovolumetric bladder contraction of low magnitude, and no significant change in bladder size or the organ’s position would have occurred as the volume of urine in his bladder did not alter. Yet a sequence of changes in chromophore concentration was observed that clearly shows variations in ΔHb and in ΔO₂Hb and ΔHHb. Based on our current understanding of the microcirculation’s role in regulating oxygen supply and demand, these changes would reflect variations in detrusor hemodynamics and oxygenation. This data sequence and elements of the chromophore change seen in the 6 symptomatic subjects reported (Fig. 3, Fig. 4) correspond to data from voluntary muscle, where variations in blood volume or increased oxygen consumption resulting in oxygen debt are generated experimentally.1,3,18,19

We recognize limitations in this report. It only has single observations in 14 asymptomatic subjects (including 4 children) and 6 symptomatic children; the magnitude of chromophore change varies between subjects; and the data analysis compared patterns of change rather than mathematical criteria. However, the patterns of change derived from the two NIRS devices were directly comparable, and the physics principles and algorithms employed in both NIRS devices were the same.13 Also, variations in chromophore magnitude are seen in NIRS studies of other tissues, and likely represent differences in light penetration and scatter.

Conclusion

NIRS monitoring, when interpreted in the context of change in detrusor oxygenation or hemodynamics, should be of interest to urologists. We observed that subjects with symptomatic prostatic obstruction had little or no increase in tHb or O₂Hb throughout their attempts to void.4,5,9 This observation parallels NIRS studies of striated muscle where muscle fatigue and symptoms of cramping occur with chromophore changes, suggesting curtailment of oxygen delivery;18 and situations in subjects with congestive heart failure where work of breathing increases during exercise associated with respiratory muscle hypo-perfusion.2 Therefore, looking at the physiologic basis for NIRS data changes occurring in voiding dysfunction is of greater potential value than reliance on algorithms with diagnostic potential.

There is a need for non-invasive devices and methodology to evaluate voiding dysfunction, particularly in children. As this pilot physiologic data indicate, NIRS can add data of potential value. There is a high level of acceptance of the device by children and wireless devices make ambulant monitoring possible. We suggest NIRS has a role in future applications of urologic research and in diagnostic evaluation.
