Abstract

We describe the case of an 89-year-old man who developed delirium following the introduction of fesoterodine to treat his urgency incontinence. The patient started experiencing visual hallucinations approximately five days after starting fesoterodine 4 mg once daily. Delirium resolved after fesoterodine was stopped. Despite the apparent safe cognitive profile due to its pharmacodynamic properties, fesoterodine should be used with caution in the elderly, frail population.

Introduction

Urgency incontinence affects up to 30% of the elderly population.¹ Antimuscarinic agents used to treat urgency incontinence may cause central nervous system (CNS) effects, such as delirium and cognitive decline.² Fesoterodine has a comparable efficacy to other antimuscarinic agents in urgency incontinence.² Fesoterodine is rapidly metabolized into its active metabolite 5-hydroxymethyl tolterodine (5-HMT). 5-HMT crosses the blood-brain barrier (BBB), but is actively transported out of the CNS by the P-glycoprotein (P-gp), which leads to a non-significant concentration in the CNS in an *in vivo* animal model.³ From the data available from clinical trials,^{4,5} some authors have stated that fesoterodine doesn't cause cognitive impairment in elderly patients. Its effect on attention, memory, and executive function was similar to placebo in a double-blind, double-dummy, crossover study on 20 healthy elderly patients aged between 65 and 84 years old.⁶ In a double-blind clinical trial involving 562 vulnerable elderly patients, no deterioration of mini-mental state examination (MMSE) score was observed; however, two subjects reported subjective impairment after an increase to fesoterodine 8 mg dose.⁷ In another trial, three patients

discontinued treatment due to an acute confusional state, but the site investigator judged it unrelated to fesoterodine.⁸ Cognitive decline was measured using memory tests (such as MMSE), which aren't as sensible for the detection of delirium as the confusion assessment method or the delirium rating scale.^{9,10} To our knowledge, delirium hasn't been formally observed with fesoterodine in the literature using delirium-specific scales. This is, therefore, the first report on delirium related to fesoterodine.

Case report

An 89-year-old man with a history of hypertension, dyslipidemia, coronary artery disease, chronic obstructive pulmonary disease, gout, stage 4 chronic kidney disease (creatinine clearance 17 ml/min), venous insufficiency with lower limb edema, liver metastases from colon neoplasia and prostate neoplasia with partial prostatectomy, and no prior history of cognitive impairment was admitted to the emergency of the Centre Hospitalier de l'Université de Montréal (CHUM) after experiencing visual hallucinations. The patient saw 50 people in his apartment and had gone to his neighbour's house to hide. After medical evaluation, he was admitted to the CHUM's geriatric ward with a diagnosis of delirium.

A complete blood work was done. Kidney function was stable according to baseline creatinine and hepatic function tests were normal. Computed tomography (CT) scan was similar to previous results. No neurological impairment, nor head trauma was reported. There were no signs of infection and metabolic markers, such as electrolytes, glycemia, and thyroid-stimulating hormone, were normal. According to his chart, the only recent change to his medication was the addition of fesoterodine at a dosage of 4 mg once daily started five days prior to the hallucination report. His other prior medications included finasteride 5 mg daily, amlodipine 5 mg daily, atorvastatin 20 mg daily, metoprolol 50 mg twice daily, furosemide 20 mg daily, bicalutamide 50 mg daily, and acetaminophen 650 mg as needed.

Fesoterodine was discontinued upon admission because it was suspected to be the cause of his delirium, but hallucination persisted for seven days. For the symptoms of delirium, risperidone 0.25 mg once daily was prescribed and increased two days later to 0.25 mg twice daily. Haloperidol was prescribed on an as-needed basis for agitation. Lorazepam 1 mg subcutaneously was administered once because haloperidol was ineffective. All risperidone and haloperidol were discontinued 14 days later, as the patient improved clinically.

Discussion

Delirium is an acute decline in cognitive function, including disorganized thinking, inattention, and altered consciousness and mental status.¹¹ It has been associated with increased hospital stay, mortality, and long-term decrease in functionality.^{9,12} Antimuscarinic agent are known to cause delirium.¹¹ Stuhc reported a case of solifenacin-induced delirium that improved once it was stopped.¹³ In a prospective cohort study of 14 526 participants (mean age 62.7 years), Layton et al reported a significant association between tolterodine and visual hallucination.¹⁴ Other cases were reported with anticholinergics used in younger and older patients.¹⁵⁻¹⁷

In this case, hallucinations stopped seven days after stopping fesoterodine. As the half-life for 5-HMT is approximately eight hours, complete elimination would be expected after 40–56 hours (5–7 half-life).¹⁸ Even if it was used at the correct dosage, fesoterodine is mainly eliminated by renal excretion and the patient's stage 4 chronic kidney disease could have slowed its elimination, explaining the lengthened duration of hallucinations.¹⁸ Indeed, a study by Malhotra et al showed a two-fold increase in C_{max} and 2.3-fold increase in area under the curve (AUC) of 5-HMT in patients with severe renal impairment (creatinine clearance <30 ml/min).¹⁹

5-HMT is inactivated by CYP 3A4 and CYP 2D6.¹⁸ The patient used finasteride, amlodipine, atorvastatin, and bicalutamide, which are CYP 3A4 inhibitors and substrate, and metoprolol, a CYP 2D6 substrate and minor inhibitor. Despite a theoretical risk of interaction with fesoterodine, none was documented in literature.^{20,21}

Diuretics may cause dehydration and hyponatremia leading to delirium.²² Furosemide also has an anticholinergic load.²³ The patient was taking furosemide for over three years with no recent dose change. No signs of dehydration and normal electrolytes suggest that furosemide contribution to delirium was unlikely.

Delirium was treated by reversing the pharmacological cause and managing the symptoms with antipsychotics, which is appropriate according to current North American recommendations.^{24,25} However, the use of benzodiazepine for agitation could have contributed to the exacerbation of the delirium.

The adverse effect in our case report was evaluated using the Naranjo adverse drug reaction probability scale and was possibly associated with fesoterodine use (4 points).²⁶

Until now, fesoterodine was known for its safe cognitive profile. The current case report raises the question whether 5-HMT can actually be in a sufficient concentration in the CNS to cause adverse reactions such as delirium in old, frail patients. The current patient is older and frailer than those included in the Kay's study.⁶ Therefore, until further research can be done, fesoterodine should be used with caution in those who might have a risk of increased drug exposure (such as renal impairment) or in those with a diminished cognitive reserve, notably the elderly and frail population.
