Abstract

Introduction: Active surveillance (AS) is an accepted management strategy for low-risk prostate cancer (PCa), but its role in the management of favorable intermediate-risk PCa remains controversial. Most reports studying the role of AS for these men generally lack long-term followup and include small numbers of patients. Our objective was to report the outcomes of men diagnosed with Gleason grade groups (GGG) 2 and 3 PCa who were managed expectantly.
Methods: Using administrative datasets and pathology reports, we identified all men who were diagnosed with GGG 2 and 3 PCa and managed expectantly between 2002 and 2011 in Ontario, Canada. Outcomes and associated factors were estimated using cumulative incidence function methods and multivariable Cox regression models, respectively.
Results: We identified 926 men who were managed expectantly (AS [n=374] or watchful waiting [n=552]). The eight-year cancer-specific survival was 94% and 89% for the AS and watchful waiting cohorts, respectively. Among AS men, 266 (71%) received treatment after a followup of approximately eight years. Cumulative AS discontinuation rates at one and five years were 30.5% and 65.1%, respectively.
Conclusions: Expectant management of GGG 2 and 3 PCa may be an option for certain men. Notably for AS patients, the cancer-specific mortality at eight years was 6%, and over 65% of men underwent treatment within five years. Further studies are required to evaluate which patients, based on disease-specific features and competing health risks, would benefit most from a conservative strategy.

Introduction

Traditionally, men diagnosed with localized prostate cancer (PCa) were treated by radical prostatectomy (RP) or a form of radiotherapy.[1] However, natural history studies have shown that only a minority of those with low- or intermediate-risk disease will develop metastases and/or succumb to the cancer.[2] Thus, active surveillance (AS) has become an accepted strategy for low-risk disease, but debated as to its application in intermediate-risk PCa.[3,4] Several large cohort studies and a randomized controlled trial have demonstrated that, for low-risk PCa, AS offers similar 10-year cancer-specific survival (CSS) compared to other well-accepted PCa treatments.[5-12] Consequently, an increasing number of men are now managed this way although rates vary worldwide.[1,9,13-15]

Reports have suggested that AS could be applied to favorable intermediate-risk PCa given that these cancers may behave in a similar fashion to low-risk PCa.[5,10,16-19] However, these experiences lack long-term followup and are generally of smaller cohorts when compared to the reports supporting AS in low-risk PCa. To our knowledge, there has not been a population-based study reporting on the long-term outcomes of Gleason Grade Groups (GGG) 2 and 3 PCa managed by AS.

Our primary objective was to report the CSS of men diagnosed with GGG 2 and 3 PCa in between 2002 and 2011 and managed expectantly, with a focus on those followed by AS. Secondary objectives were to: 1) determine the overall survival (OS) of men with GGG 2 and 3 PCa managed expectantly; 2) estimate the discontinuation rate from AS; 3) investigate characteristics associated with cancer-specific, overall and treatment-free survivals; and 4) report use of primary androgen deprivation therapy (ADT).

Methods

Study design

This was an institutional review board-approved, population-based study. Men diagnosed with PCa were identified using linked administrative databases. In Ontario, nearly all medical procedures are reimbursed by a single-payer system, the Ontario Health Insurance Plan (OHIP).[20] The OHIP database was used to identify all PCa-related interventions (Supplementary Table 1; available at *cuaj.ca*). Transrectal or transperineal ultrasound-guided biopsy pathology reports were obtained from Cancer Care Ontario and were manually abstracted by two trained abstractors. The procedure codes and the abstracted data were then linked deterministically to several other administrative databases.

Population

The cohort consisted of men diagnosed with GGG 2 or 3 PCa in Ontario between 2002 and 2011. We excluded men whose diagnostic procedure was not a transrectal or transperineal ultrasound-guided biopsy and men with <1 year of followup. Men who were treated without a prior confirmatory biopsy (defined as the second biopsy following the diagnostic one) or with a confirmatory biopsy performed within 14 days of treatment were also excluded (i.e., biopsy likely done at the time of treatment) (Supplementary Fig. 1; available at *cuaj.ca*). All men who had a confirmatory biopsy with or without treatment thereafter were considered to have been managed by AS, while men who had no confirmatory biopsy and did not undergo definitive treatment were considered to have been managed by watchful waiting (WW).

All localized GGG 2 and 3 PCa were included in this study, regardless of the digital rectal exam (DRE) and/or prostate-specific antigen (PSA) levels, as these variables were not completely captured in any of the administrative databases.

Outcomes

The primary outcome measured was CSS. Secondary outcomes were OS, discontinuation of AS, and use of primary ADT. Survival outcomes were obtained using data from the Ontario Cancer Registry and from the Registered Persons Database.[21,22] Cause of death was available up to December 31, 2012 while data for treatment and vital status were available up to December 31, 2014. Administrative codes used to identify treatments and use of ADT are detailed in Supplementary Table 1 (available at *cuaj.ca*) and have previously been shown to have high accuracy.[23,24]

Covariates

We used administrative databases to obtain a comprehensive set of covariates for risk adjustment. These included individual-, disease-specific, physician- and institution-level characteristics (Supplementary Table 2; available at *cuaj.ca*). Individual-level characteristics included age at diagnosis, year of diagnosis, neighbourhood income quintile, area of residency, initial management, and comorbidities. The aggregated diagnostic groups (ADG) score, derived from the Johns Hopkins University Adjusted Clinical Group® case mix system, was used as a proxy for the patient's comorbidities.[25] Disease-specific characteristics included PSA level and GGG at diagnosis, number of cores taken, number of positive cores, percentage of maximal core involvement at the initial and confirmatory biopsies as well as the timing of the confirmatory transrectal ultrasound-guided biopsy, where applicable. Physician-level characteristics included specialty of the treating physicians and their annual new PCa case volume, whereas institution-level characteristics included the type of treating centers and their annual new PCa case volume. The treating physician was defined as the physician who claimed the most PCa-related visits for each patient during the first 12 months after diagnosis, while the treating center was defined as the center where the patient received the majority of his PCa care during the same timeframe.

Statistical analysis

Baseline characteristics were reported using descriptive statistics and compared using Wilcoxon and Student's t-tests for medians and means, respectively, and chi-squared tests for categorical variables.

Time on AS and time to death (where applicable) were calculated from the date of diagnosis to the date when patients experienced an event (treatment or death) or were censored (i.e., end of followup period [December 31, 2014] or lost to followup [date of last contact with OHIP]). The treatment-free, ADT-free, cancer-specific, and overall survivals were estimated using cumulative incidence function methods. Their associated factors were evaluated using Cox proportional hazard (PH) models fit for a priori-defined variables (OS) or fit with variables using a stepwise regression process (treatment-free and cancer-specific survivals) and adjusted for physician- and institution-level clusters assuming cross-classified data (i.e., physicians could work in more than one institution).[26] Estimates in the multivariable models are reported as hazards ratios (HRs) with corresponding 95% confidence intervals (CIs). PH assumptions were assessed by examining residuals and with log-log plots. Fine and Gray models were also performed to account for competing risks. However, given that Cox PH and competing risk models yielded similar results, we have opted to present the Cox PH

models for ease of interpretation. All statistical analyses were performed using SAS 9.4 and R version 3.1.3. All statistical tests were two-sided, and p-values <0.05 were considered statistically significant.

Results

A total of 4040 patients with GGG 2 or 3 PCa at diagnosis were identified. Of these, 3179 were excluded because they did not meet our inclusion criteria. Most (n=2179)

were excluded because they received treatment without a prior confirmatory biopsy within one year of diagnosis (Supplementary Fig. 1; available at *cuaj.ca*). Consequently, the study cohort included 926.

Table 1 shows the demographics and disease characteristics of the cohort according to initial management. Men on WW (n=553) were significantly older than men on AS (n=374). Likewise, their median PSA at diagnosis, GGG, number of cores positive for cancer, and maximal percentage of core involvement were all significantly higher.

For men on AS, the median number of biopsies after diagnosis was 2 (interquartile range [IQR] 2–3), with a median time from diagnosis to confirmatory biopsy of 9.3 months (IQR 3.4–21). On these confirmatory biopsies, 27% (n=102) were downgraded to GGG 1 or were negative (Table 2).

Survival outcomes

After a median followup of 91 months (IQR 60–116), 371 (40%) deaths were identified. When followup time was limited to December 31, 2012 (when cause of death was available), 260 (28%) deaths were identified, of which 63 (24%) were due to PCa. Significantly more deaths due to PCa were identified in the WW group than in the AS group (48 [9%] vs. 15 [4%]; p=0.006) (Supplementary Table 3; available at *cuaj.ca*). In the AS cohort, 7 (3%) PCa-related deaths were reported in GGG 2 after eight years, while 6 (7%) were reported in the GGG 3 (Supplementary Table 4; available at *cuaj.ca*). Interestingly, of all men who died from PCa, only 5 (8%) received some form of ADT during their last year of life. The five- and eight-year CSS were 98% and 94% for the AS cohort and 94% and 89% for the WW cohort, respectively. Overall, these men were four times more likely to die from causes other than PCa (Supplementary Tables 3, 4; available at *cuaj.ca*).

†Data missing in 155 (41%) patients. IQR: interquartile range; SD: standard deviation.

On multivariable analysis (Table 3), older age, higher GGG at diagnosis, and higher maximal percentage of core involvement at diagnosis were strong predictors of higher PCa mortality. Factors associated with overall mortality are shown in Supplementary Table 5 (available at *cuaj.ca*).

Treatment-free survival

After a median followup of 97 months (IQR 72–121), 266 (71%) patients had discontinued AS. Among the patients who discontinued AS, an equal number of patients were treated with RP and radiotherapy (n=119 [45%] for both therapeutic approaches). The remaining 28 (11%) patients were managed with ADT alone (median time to initiation was 26 months [IQR15–38]). Most men who discontinued AS did so following confirmatory biopsy (n=179; 67.3%). The apparent reasons for discontinuation of AS are summarized in Table 4. Of the men who underwent a RP, 25 (21.0%) were found to have a lower GGG than at diagnosis, while 22 (18.5%) were upgraded (Supplementary Table 6; available at *cuaj.ca*).

The median time to discontinuation of AS was 59 months (IQR 23–101). Cumulative discontinuation rates at one and five years were 30.5% and 65.1%, respectively. When stratified by GGG at diagnosis, the five-year discontinuation rates were 63.5% and 69.9% for GGG 2 and 3, respectively (Fig. 1). Factors associated with decreased discontinuation within the first five years were older age, being diagnosed in the earliest year of the study period, being downgraded or having a negative confirmatory biopsy, and having a lower number of positive cores at confirmatory biopsy. Patients whose primary treating physician was a urologist and patients managed in non-specialized cancer centers were also less likely to discontinue AS (Table 5).

Discussion

The role of AS for GGG 2 and 3 remains controversial. To our knowledge, this is the largest population-based study describing the outcomes of expectant management for these men. Our results demonstrated that 4% and 11% of men managed by AS and by WW, respectively, died of PCa during the first eight years of followup. Unsurprisingly, PCa-related deaths were more common among men with GGG 3 diseases than among men with GGG 2 cancers. Interestingly, of these men, only 8% received some form of ADT during their last year of life. Therefore, one could speculate that although PCa was specified as their cause of death, it is entirely plausible that many died of other causes. Nevertheless, even with this possibility in mind, men managed expectantly were four times more likely to die from non-PCa related causes.

Additionally, over 65% of men on AS were treated within five years, including 6% with primary ADT. Factors associ-

ated with AS discontinuation included age, year of diagnosis, and total number of positive cores at the confirmatory biopsy. Interestingly, men treated by radiation oncologists or in dedicated cancer centers were more likely to undergo treatment during followup. Although this could indicate a practice pattern, it is also plausible that the association is more reflective of a referral pattern than a true treatment philosophy. In addition to these aforementioned factors, our results also demonstrated that men who were downgraded to GGG 1 or

who had a negative confirmatory biopsy were significantly less likely to discontinue AS within five years of diagnosis.

The survival outcomes reported here are in line with several previously published reports. These studies have reported cancer-specific mortality rates for men with intermediate-risk PCa managed by AS varying from 0–4% after a followup ranging from 28–80 months.[7,11,16-19] Importantly, the outcomes reported by these studies are no different to the outcomes of men with similar disease who have undergone

Table 4. Number of transrectal ultrasound biopsy before discontinuation of active surveillance and the apparent reasons for the discontinuation (n=266 men who underwent treatment)

Number of biopsy before discontinuation	n (%)
After second (confirmatory) biopsy	179 (67%)

treatment. Based on data from the National Prostate Cancer Register of Sweden, Stattin et al have reported a 10-year

Fig. 1. Active surveillance discontinuation rates over 10 years. GG: Gleason grade group.

CSS of 96.6% and 96.2% after RP and radiation therapy, respectively.[27] Similar numbers (95% CSS) were reported by Stephenson et al at 10-year followup for patients who underwent a RP for GGG 2 and 3 PCa.[28] Thus, the evidence suggests that, at the very least, a subset of GGG 2 and 3 PCa patients could be managed with AS while avoiding some of the potential complications associated with PCa treatments.

In spite of the reassuring survival outcomes, the definitive treatment rate was higher than that published in previous reports, with rates historically varying from 29–61%.[7,11, 16-19] One of the possible explanations for our higher rates, in addition to longer followup when compared to previous publications, is the fact our study only included men that were considered as intermediate-risk PCa based solely on their GGG and not on their PSA level or DRE. In comparison, in the previously reported studies of men with intermediate-risk PCa managed by AS, the proportion of men included with GGG 2 and 3 PCa varied from 22–63%.[7,11,16-19] Regardless, one needs to remember that nearly 30% of men in our cohort avoided the potential complications of PCa treatment by choosing AS.

Although this study reports the outcomes of the largest GGG 2 and 3 PCa cohort managed expectantly, it is not devoid of limitations. The study was based on administrative databases and lacks the granularity of prospective studies. Because of this, data for some variables were incomplete (PSA values, number of positive cores at confirmatory biopsy, etc.) or were not captured (DRE findings, metastatic state, etc.). Likewise, as the cause of death was not available after 2012, our results may have underestimated the proportion of patients who died from PCa during the study period. As demonstrated by our rates of upgrading at confirmatory biopsy, and as suggested by others, it is entirely possible that the initial biopsy underestimated the true extent of the disease.[29] Additionally, 6% of patients were started on primary ADT during followup, which is thought to be a proxy for metastatic disease. Therefore, it is possible that longer followup would have found more PCa-related deaths and/or metastatic diseases. The study also lacks information on family history, race, and use of diagnostic imaging, such as multiparametric magnetic resonance imaging. Moreover, we defined AS patients as those who received a confirmatory biopsy. This definition likely introduced a certain selection bias, as it is well-known that not all AS patients will undergo a confirmatory biopsy.[16,30] Lastly, this study lacks a comparative treatment arm. Consequently, this limited our conclusions with regard to which patients were ideal candidates for AS and what the triggers for intervention should be. Nevertheless, our results indicated that older men and men with more favorable findings on the diagnostic biopsy (i.e., GGG 2 and ≤50% maximal core involvement) were less likely to die from PCa and, thus, may potentially be better candidates.

[†]Variables significant in univariate model were selected for multivariable model, and a stepwise selection approach was used for the final multivariate model. ADG: aggregated diagnosis group; CI: confidence interval; HR: hazard ratio; PSA: prostate specific antigen.

Conclusions

Expectant management of GGG 2 and 3 PCa remains an option for certain men, as many will succumb to a non-PCa-related death. Nevertheless, men on AS had a 6% cancer-specific mortality at eight years after diagnosis, and more than 65% of them were treated within five years. It is clear this option should not be applied to all GGG 2 and 3 patients. Further studies are required to evaluate which subgroup of patients would benefit most from a conservative approach. Men with GGG 2 and 3 PCa opting for this strategy should fully understand the potential benefits and harms of this approach and the high likelihood of eventually undergoing treatment.
